What Are Gamma-Ray Bursts?
The Unique Role of Very High Energy Gamma-Ray Observations

Abstract
Gamma-ray bursts (GRBs) have been an enigma since their discovery forty years ago. However, considerable progress unraveling their mysteries has been made in recent years. Developments in observations, theory, and instrumentation have prepared the way so that the next decade can be the one in which we finally answer the question, “What are gamma-ray bursts?” This question encompasses not only what the progenitors are that produce the GRBs, but also how the enormous luminosity of the GRBs, concentrated in gamma rays, is achieved. Observations across the electromagnetic spectrum, from both the ground and space, will be required to fully tackle this important question. This white paper, mostly distilled from a recent study commissioned by the Division of Astrophysics of the American Physical Society, focuses on what very high energy (∼100 GeV and above) gamma-ray observations can contribute. Very high energy gamma rays probe the most extreme high energy particle populations in the burst environment, testing models of lepton and proton acceleration in GRBs and constraining the bulk Lorentz factor and opacity of the outflow. Sensitivity improvements of more than an order of magnitude in the very high energy gamma-ray band can be achieved early in the next decade, in order to contribute to this science.

Introduction
Much has been learned since the discovery of gamma-ray bursts (GRBs) in the late 1960s. There are at least two classes of GRB, most conveniently referred to as “long” and “short,” based primarily on the duration and spectral hardness of their prompt sub-MeV emission. The characteristics of the host galaxies—their types and star formation rates—suggest different progenitors for these two classes. The exact nature of the progenitors nevertheless remains unknown, although it is widely believed that long GRBs come from the deaths of massive, rapidly rotating stars and short GRBs result from compact object mergers. The unambiguous solution to this mystery is critical to astrophysics since it has fundamental importance to several topics, including stellar formation history and ultra high energy cosmic-ray acceleration. Equally important is an understanding of how GRBs process the energy of the explosion into the observed gamma-ray luminosity. A detection of very high energy (VHE, ∼100 GeV and above) γ-ray emission from GRBs would severely constrain the physical parameters pertaining to the particle acceleration by GRBs and the energy injected into the particle acceleration sites. These observations would constrain models for particle acceleration in bursts, and the total energy budget could constrain the properties of the GRB progenitors themselves.

The evidence indicates that GRBs involve collimated, relativistic outflows or jets, and one of the big questions is whether the jets are dominated by ultrarelativistic protons, which interact with either the radiation field or the background plasma, or are dominated by e⁺e⁻ pairs. The combination of the Fermi Large Area Telescope (LAT) and current generation VHE telescopes will contribute to progress on these questions in the near term, but more sensitive observations will be needed for a full explanation.

The same shocks which are thought to accelerate electrons responsible for non-thermal γ-rays in GRBs should also accelerate protons. The shocks are expected to be mildly relativistic and to lead to relativistic protons. The maximum proton energies achievable in GRB shocks are estimated to be ∼10^{20} eV, comparable to the highest energies of the mysterious ultra
high energy cosmic rays measured with large ground arrays. The accelerated protons can interact with fireball photons, leading to pions, followed by high energy gamma rays, muons, and neutrinos. Photopion production is enhanced in conditions of high internal photon target density, whereas if the density of (higher-energy) photons is too large, the fireball is optically thick to gamma rays, even in a purely leptonic outflow. High energy gamma-ray studies of GRBs provide a direct probe of the proton shock acceleration as well as of the photon density.

Most of the information presented in this white paper has been condensed from a more lengthy report [1] by the Gamma-Ray Burst Working Group for the study, “The Status and future of ground-based TeV gamma-ray astronomy,” completed in 2008 in response to a commission from the Division of Astrophysics of the American Physical Society. Detailed references, provided in that report, are not repeated here.

### Theoretical Expectations

Very high energy gamma rays are a natural consequence of many of the processes thought to occur in GRBs. The details of the presence or absence, spectrum and light curve of such emission can serve to illuminate which processes in fact take place in a particular burst. A brief discussion of some of the key theoretical ideas follows.

Gamma-ray burst $\nu F_\nu$ spectral energy distributions peak at photon energies ranging from a few keV to several MeV and are not thermal. From EGRET (and early Fermi-LAT data [2]), it is clear that the spectra extend to at least several GeV. The most widely accepted scenario is the conversion of energy from an explosion into kinetic energy of a relativistic flow. At a second stage, the kinetic energy is converted into radiation via internal collisions (the internal shock model) resulting from variability in the ejection from the progenitor or an external collision (the external shock model) with the surrounding medium. The collisions produce shocks, which enhance and are believed to create magnetic fields, as well as to accelerate electrons to high energies. In the standard theoretical model, this initial burst of emission, the so-called prompt emission, is followed by afterglow emission from an external shock that moves through the circumburst environment.

An alternative way of producing the emission involves conversion of the explosion energy into magnetic energy, which produces a flow that is Poynting-flux dominated. The emission is produced following dissipation of the magnetic energy via reconnection of the magnetic field lines. An apparent advantage of this model over the internal or external shock model is that the conversion of energy to radiation in principle can be much more efficient. The microphysics of the reconnection process in this model, like the microphysics determining the fraction of energy in relativistic electrons and in the magnetic field in the internal and external shock scenarios, is not yet fully understood.

VHE observations probe the extremes for each of these models and simultaneously probe the environment where the emission originated.

The leading emission mechanism employed to interpret the GRB prompt emission in the keV-MeV band is nonthermal synchrotron radiation, although even this is far from certain forty years after its discovery. An order of magnitude estimate of the maximum observed energy of photons produced by synchrotron emission proceeds as follows: Assuming that the electrons are Fermi accelerated in the shocks, the maximum Lorentz factor of the accelerated electrons $\gamma_{\text{max}}$ is found by equating the particle acceleration time and the synchrotron cooling time, yielding $\gamma_{\text{max}} = 10^5/\sqrt{B/10^6}$, where $B$ is the magnetic field strength in gauss. For relativistic motion with bulk Lorentz factor $\Gamma$ at redshift $z$, synchrotron emission from
electrons with $\gamma_{\text{max}}$ peaks in the observer’s frame at energy $70 \left( \Gamma/315 \right) (1 + z)^{-1}$ GeV, which is independent of the magnetic field. Thus, synchrotron emission can produce photons with energies up to, and possibly exceeding, $\sim 100$ GeV.

A natural emission mechanism that can contribute to emission at high energies ($\gtrsim$ MeV) is inverse-Compton (IC) scattering. The seed photons for the scattering can be synchrotron photons emitted by the same electrons, namely synchrotron self-Compton (SSC) emission. The seed photons can also be thermal emission originating from the photosphere, an accretion disk, an accompanying supernova remnant, or supernova emissions in two-step collapse scenarios. Compton scattering of photons can produce emission up to observed energies $15 \left( \gamma_{\text{max}}/10^5 \right) \left( \Gamma/315 \right) (1 + z)^{-1}$ TeV, well into the VHE regime.

The shapes of the Comptonized emission spectra in GRBs depend on the spectra of the seed photons and the energy and pitch-angle distributions of the electrons. A thermal population of electrons can inverse-Compton scatter seed thermal photons or photons at energies below the synchrotron self-absorption frequency to produce the observed peak at sub-MeV energies. Since the electrons cool by the IC process, a variety of spectra can be obtained. Comptonization can produce a dominant high energy component that can explain hard high-energy spectral components, such as that observed in GRB 941017. Prolonged higher energy emission could potentially be observed with a sensitive VHE gamma ray instrument.

The maximum observed photon energy from GRBs is limited by the annihilation of gamma rays with target photons, both extragalactic IR background and photons local to the GRB, to produce electron-positron pairs. This limit is sensitive to the uncertain value of the bulk motion Lorentz factor as well as to the spectrum at low energies, and is typically in the sub-TeV regime. Generally, escape of high-energy photons requires large Lorentz factors. In fact, observations of GeV photons have been used to constrain the minimum Lorentz factor of the bulk motion of the flow, and spectral coverage up to VHE energies could further constrain the Lorentz factor. If the Lorentz factor can be determined independently, e.g. from afterglow modeling, then the annihilation signature can be used to diagnose the gamma-ray emission region.

The evidence for acceleration of leptons in GRB blast waves is based on fitting lepton synchrotron spectra models to GRB spectra. This consistency of leptonic models with observed spectra still allows the possibility of hadronic components in these bursts, and perhaps more importantly, GRBs with higher energy emission have not been explored for such hadronic components due to the lack of sensitive instruments in the GeV/TeV energy range. The crucially important high-energy emission components, represented by a few EGRET bursts, a marginal significance Milagrito TeV detection, and now GRB 080916C [2], have been statistically inadequate to look for correlations between high-energy and keV/MeV emission that can be attributed to a particular process. Indeed, the prolonged high-energy components in GRB 940217 and the “Superbowl” burst, GRB 930131, and the anomalous gamma-ray emission component in GRB 941017, behave quite differently than the measured low-energy gamma-ray light curves. Therefore, it is quite plausible that hadronic emission components are found in the high energy spectra of GRBs.

Several theoretical mechanisms exist for VHE $\gamma$-ray emission from hadrons. Accelerated protons can emit synchrotron radiation in the GeV–TeV energy band. The power emitted by a particle is $\propto \gamma^2/m^2$, where $\gamma$ is the Lorentz factor of the particle and $m$ is its mass. Given the larger mass of the proton, to achieve the same output luminosity, the protons have $\sim 1836$ times higher mean Lorentz factor, the acceleration mechanism must convert $\sim$
3 million times more energy to protons than electrons and the peak of the proton emission would be at $\gtrsim 2000$ times higher energy than the peak energy of photons emitted by the electrons. Alternatively, high-energy baryons can produce energetic pions, via photomeson interactions with low energy photons, creating high-energy photons and neutrinos as the pions decay. This process could be the primary source of ultra high energy (UHE) neutrinos. Correlations between gamma-ray opacity and bulk Lorentz factor from measurements with sensitive VHE $\gamma$-ray telescopes can test for UHE cosmic-ray production. Finally, proton-proton or proton-neutron collisions may also be a source of pions, and in addition, if there are neutrons in the flow, then the neutron $\beta$-decay has a drag effect on the protons, which may produce another source of radiation. Each of these cases has a VHE spectral shape and intensity that can be studied coupled with the emission measured at lower energies and with neutrino measurements.

Afterglow emission is explained in synchrotron-shock models by the same processes that occur during the prompt phase. However, unlike the prompt phase, there are optical and near infrared linear polarization measurements to support the synchrotron interpretation. The key difference is that the afterglow emission originates from large radii, $\gtrsim 10^{17}$ cm, as opposed to the much smaller radius of the flow during the prompt emission phase, $\sim 10^{12} - 10^{14}$ cm for internal shocks, and $\sim 10^{14} - 10^{16}$ cm for external shocks. As a result, the density of the blast-wave shell material is smaller during the afterglow emission phase than in the prompt phase, and some of the radiative mechanisms, e.g. thermal collision processes, may become less important. The lower density also reduces the expected photon pair opacity, enabling VHE gamma rays to more readily escape, if produced.

**Status of Observations**

One definitive observation of prompt or afterglow VHE $\gamma$-ray emission could significantly improve our understanding of the processes at work in the GRB and its aftermath. Although many authors have predicted such emission, the predictions are near or below the sensitivity of current instruments, and there has been no definitive detection of VHE emission from a GRB either during the prompt phase or at any time during the afterglow. The detection of a 13 GeV photon by the *Fermi*-LAT from GRB 080916C [2] at a redshift of 4.35±0.15 [3] shows that photons with at least 70 GeV can be produced by GRBs.

For the observation of photons of energies above 300 GeV, only ground-based telescopes are suitable. These ground-based telescopes fall into two broad categories, air shower arrays and imaging atmospheric Cherenkov telescopes (IACTs). The air shower arrays, which have wide fields of view that are suitable for GRB searches, are relatively less sensitive. There are several reports from these instruments of possible TeV emission: emission $>16$ TeV from GRB 920925c, an indication of 10 TeV emission in a stacked analysis of 57 bursts, and an excess gamma-ray signal during the prompt phase of GRB 970417a. In all of these cases however, the statistical significance of the detection is not high enough to be conclusive. In addition to searching the Milagro data for VHE counterparts for over 100 satellite-triggered GRBs since 2000, the Milagro Collaboration conducted a search for VHE transients of 40 seconds to 3 hours duration in the northern sky; no evidence for VHE emission was found from these searches.

IACTs have better flux sensitivity and energy resolution than air shower arrays, but are limited by their small fields of view ($\sim 3-5^\circ$), which require retargeting to the GRB position, and low duty cycle ($\sim 10\%$). Follow-up observations on many GRBs have been made by the MAGIC, VERITAS, and HESS groups, with upper limits typically around 5% of the Crab
flux or better. MAGIC observations of GRB 050713a began only 40 seconds after the prompt emission, demonstrating the fast slewing capability of that instrument.

One of the main obstacles to VHE detection of GRBs is their distance. Pair production interactions of gamma rays with the infrared photons of the extragalactic background light attenuate the gamma-ray signal, limiting the distance over which VHE gamma rays can propagate. The MAGIC Collaboration has reported the VHE detection of the flat spectrum radio quasar 3C279, at redshift 0.536. This represents a large increase in distance to the furthest detected VHE source, revealing more of the universe to be visible to VHE astronomers than was previously thought.

**Observations in the Next Decade**

Ground-based observations of VHE emission from GRBs are difficult. Nevertheless, instruments planned for the next decade likely will be able to detect the VHE component of GRBs, which could open a new way to understand as well as discover them. The fraction of bursts close enough to elude attenuation at VHE energies by the extragalactic background

---

**Figure 1:** The sensitivity of high-energy gamma-ray instruments for 1 minute observations of an object in the field of view. AGIS, CTA and HAWC are concepts for state-of-the-art instruments which could be realized in the next decade and which improve upon the sensitivity of current instruments of the same type by an order of magnitude or more. AGIS and CTA are narrow-field ($\sim 5–10^\circ$) Cherenkov telescope arrays which operate at night; HAWC is a wide-field ($\sim 2$ sr) air shower array which operates around the clock. The AGIS/CTA curve (solid blue) is the differential sensitivity for 0.25 decade bins, while for HAWC (dashed blue) 0.5 decade bins are assumed. The dotted blue curve shows the sensitivity of the *Fermi*-LAT (“GLAST”). The sensitivity curves are based on a 5$\sigma$ detection and at least 25 detected photons in each bin. Also shown are plots of the predicted gamma-ray spectra for a GRB at a redshift of $z=1$ adapted from Pe’er and Waxman [4], reduced by a factor of 10 to illustrate the sensitivity even to weaker bursts. The green and red curves show the calculation for a wind environment and an ISM-like environment. The dotted curves give the source spectrum, while the solid curves include the effects of extragalactic background light absorption using the model of Franceschini *et al.* [5]. Black points and error bars (not visible) are simulated independent spectral points that could be obtained with AGIS/CTA.
light is small. Only $\sim 10\%$ of long bursts have redshift $<0.5$, the redshift of the most distant detected VHE source. Roughly half of short burst redshifts are $<0.5$, but the prompt emission has ended prior to satellite notifications of the burst location. The reach of VHE instruments can be extended by lowering the energy threshold, since the attenuation is a rapidly rising function of energy. The GRBs that will be detected from the ground will preferentially be nearby, making them excellent candidates for multiwavelength and multimessenger (e.g. LIGO for neutron star mergers or IceCube for neutrino production) observations.

Wide field of view detectors with high duty cycle operations would be ideal to observe the prompt emission from gamma-ray bursts. Imaging atmospheric Cherenkov telescopes (IACT) can be made to cover large sections of the sky by either having many mirrors each pointing in a separate direction or by employing secondary optics to expand the field of view of each mirror. However, the duty factor is still $\sim 10\%$ due to solar, lunar, and weather constraints. IACTs could also be made with fast slewing mounts to allow them to slew to most GRBs within $\sim 20$ seconds, thus allowing them to observe some GRBs before the end of the prompt phase. Alternatively, extensive air shower detectors intrinsically have a field of view of $\sim 2$ sr and operate with $\sim 95\%$ duty factor. These observatories, especially if located at very high altitudes, will have $\sim 100$ m$^2$ of sensitive area at 100 GeV and be more sensitive than Fermi-LAT above 100 GeV, but with poor energy resolution. IACT arrays will be able to achieve a sensitivity of $10^{-9}$ erg s$^{-1}$ cm$^{-2}$ (in $\lesssim 20$ sec integration), or better, sufficient to probe a substantial fraction of models for high-energy emission from those bursts which they are able to observe. The combined observations of both of these types of detectors would yield the most complete picture of the prompt high energy emission.

Observational VHE $\gamma$-ray astrophysics is young, and substantial headway has been made in recent years understanding the performance and limitations of present instruments. As a result, concepts for next-generation instruments of both the extensive air shower and imaging atmospheric Cherenkov telescope design are at hand and could be realized early in the next decade. In both cases, improvements of more than an order of magnitude in sensitivity are projected. The expected sensitivity of the two techniques is shown in Figure 1.

The detector strategy for extended emission associated with traditional afterglows or with late-time flares from GRBs is far simpler than the strategy for early prompt emission. The high sensitivity and low energy threshold of an IACT array are the best way to capture photons from this emission at times greater than $\sim 1$ min, particularly if fast slewing is included in the design.

**Summary**

Gamma-ray bursts undoubtedly involve a population of high-energy particles responsible for the emission detected from all bursts (by definition) at energies up to of order 1 MeV, and for a few bursts so far observable by EGRET and Fermi-LAT, up to a few GeV. Gamma-ray bursts may in fact be the source of the highest energy particles in the universe. In virtually all models, this high-energy population can also produce VHE gamma-rays, although in many cases the burst environment would be optically thick to their escape. The search for and study of VHE emission from GRBs therefore tests theories about the nature of these high energy particles (Are they electrons or protons? What is their spectrum?) and their environment (What are the density and bulk Lorentz factors of the material? What are the radiation fields? What is the distance of the emission site from the central source?). In addition, sensitive VHE measurements would aid in assessing the the total bolometric radiation output from bursts. Knowledge of the VHE gamma-ray properties of bursts will
therefore help complete the picture of these most powerful known accelerators.

An example of the insight that can be gleaned from VHE data is that leptonic synchrotron/SSC models can be tested, and model parameters extracted, by correlating the peak energy of X-ray/soft $\gamma$-ray emission with GeV–TeV data. For long-lived GRBs, the spectral properties of late-time flaring in the X-ray band can be compared to the measurements in the VHE band, where associated emission is expected. Of clear interest is whether there are distinctly evolving high-energy $\gamma$-ray spectral components, whether at MeV, GeV or TeV energies, unaccompanied by the associated lower-energy component expected in leptonic synchro-Compton models. Emission of this sort is most easily explained in models involving proton acceleration. As a final example, the escape of VHE photons from the burst fireball provides a tracer of the minimum Doppler boost and bulk Lorentz motion of the emission region along the line of site, since the inferred opacity of the emission region declines with increasing boost.

There are observational challenges for detecting VHE emission during the initial prompt phase of the burst. The short duration of emission leaves little time (tens of seconds) for repointing an instrument, and the opacity of the compact fireball is at its highest. For the majority of bursts having redshift $\gtrsim 0.5$, the absorption of gamma rays during all phases of the burst by collisions with the extragalactic background light reduces the detectable emission, more severely with increasing gamma-ray energy. With sufficient sensitivity, an all-sky instrument is the most desirable for studying the prompt phase, in order to measure the largest sample of bursts and to catch them at the earliest times. The techniques used to implement all-sky compared to pointed VHE instruments result in a trade-off of energy threshold and instantaneous sensitivity for field of view. More than an order of magnitude improvement in sensitivity to GRBs is possible now for the next-generation instruments of both types, giving both approaches a role in future studies of GRB prompt emission.

The detection of VHE afterglow emission, delayed prompt emission from large radii, and/or late X-ray flare-associated emission simply requires a sensitive instrument with only moderate slew speed. It is likely that an instrument with significant sensitivity improvements over the current generation of IACTs will detect GRB-related VHE emission from one or all of these mechanisms which do not suffer from high internal absorption, thus making great strides towards understanding the extreme nature and environments of GRBs and their ability to accelerate particles.

In conclusion, large steps in understanding gamma-ray bursts have frequently resulted from particular new characteristics measured for the first time in a single burst. New instruments improving sensitivity to VHE $\gamma$-rays by an order or magnitude or more compared to existing observations have the promise to make just such a breakthrough in the VHE band during the next decade, helping to answer the question, “What are gamma-ray bursts?”
